March 2014

Abstract

This paper explores the relation between institutional quality, trust and stock market participation. In our theoretical motivation, agents update their beliefs in a Bayesian manner based on their historical observations on frauds and they choose to invest in the stock market if their subjective probability of fraud is sufficiently low. In accordance with this theoretical motivation, we develop an empirical model, which tests the hypothesis that higher institutional quality is likely to lead to a higher level of trust, together with the hypothesis that when the level of trust is sufficiently high, agents choose to invest in the stock market. We use a large sample of European (SHARE survey) data on households residing in fourteen European countries that have a large variation in institutional quality. We find that institutional quality has a significant effect on trust and that trust (particularly the part that is explained by institutional quality) in turn significantly affects stock market participation. Moreover, our model takes into account the learning process of immigrants, who experience a dramatic change in institutional quality. We find that the probability that an immigrant participates in the stock market increases both with the institutional quality of the country of residence and that of the country of origin. However, on average, the former is more influential than the latter. We also find that immigrants with a higher level of education adapt their level of trust faster to the institutional environment of the country of residence than those with a lower level of education. The impact of the institutional quality of the immigrants’ country of residence on stock market participation, relative to that of their country of origin, tends to increase with education.

Keywords: institutional quality, learning, trust, limited participation puzzle

Friedrich Nietzsche, “The Use and Abuse of History”

1. Introduction

The ability to protect property rights is paramount to the development of financial markets and also to promoting economic growth in a market economy. If people trust that financial contracts are being enforced and that the cost of fraudulent behavior is sufficiently high then, presumably, they are also more likely to invest. In an environment of low institutional quality where property rights are not being protected and there is no substantial punishment for fraudulent behavior, people become distrustful and less willing to engage in any type of financial contract that involves a counterparty to whom they have no personal ties. In such environments, social control becomes more important and may in some cases partially (at least locally) replace the punishing role of institutions. However, social control can never entirely replace the role of institutions, because social control applies only locally, whereas institutions have a much broader impact on attitudes and behavior. In well-functioning market economies with good institutions, people tend to trust each other and therefore they also enter financial contracts with counterparties with whom they have no previous ties.1

In this paper, we analyze the effects of institutional quality on stock market participation, both theoretically and empirically. We develop a theoretical model in which agents are Bayesian updaters who from time to time observe frauds, and this will form their level of trust. According to the model, higher institutional quality leads to a higher level of trust, and for a sufficiently high level of trust, agents want to invest in the stock market.

---

1 See Bohnet and Steffen (2004) for evidence that better institutions lead to higher levels of trust.
To the best of our knowledge, this is the first study on the effect of institutional quality on the degree of stock market participation, which accounts for the learning aspect in individuals’ behavioral response to institutional quality.

We investigate the extent to which trust related to institutional quality affects individual investors’ stock market participation. An interesting aspect resides in the fact that people may migrate to other countries and experience a dramatic change in institutional quality. Over time, they should adopt a level of trust that is consistent with the institutional quality of their new country of residence and the degree of fraud in their country of origin should play a less important role in their decision making. However, many factors may affect the speed by which individuals adapt to a new country of residence. In our theoretical model, we make the behavioral assumption that immigrants use a weighted average of fraud probabilities in their home country and in their new country of residence.

In accordance with our theoretical motivation, we build an empirical model, which investigates to what extent institutional quality affects trust and how both the part of trust that is explained by institutional quality and the part of trust that cannot be explained by institutional quality affect stock market participation. In the case of immigrants, we analyze to what degree their level of trust is affected by the institutional quality of their home country relative to that of their new country of residence. Furthermore, we study if immigrants’ degree of adaptation in this regard is related to their level of education.

We find strong support for our hypotheses: institutional quality significantly affects trust and the level of trust that is related to institutional quality has in turn a significant effect on the probability of stock market participation. Further, we find that immigrants’ education is an important factor determining the relative impact of the institutional quality of the country of residence relative to that of the home country: the more time the immigrant households have spent on education, the larger is the impact of the institutional quality of the country of
residence. Our interpretation is that highly educated immigrants learn the institutional quality of their new country of residence faster and assign a higher weight to it, whereas poorly educated immigrants are to a larger extent influenced by the institutional quality of their home countries. Our study is based on European survey data (the SHARE data set), covering more than 30,000 individuals in fourteen European countries. We first employ an ordered probit model to investigate the relation between trust and institutional quality, in which the relative weight assigned by immigrants to the institutional quality of the country of residence and the country of origin is determined endogenously within the model, and is allowed to be a function of the immigrant’s level of education. In the second step, we perform a standard probit analysis of the relationship between stock market participation and trust related to institutional quality.

We contribute to the literature on the “limited participation puzzle.” The theoretical explanations that have been put forward for this phenomenon include both rational ones, based on, e.g., transaction costs and liquidity needs (Allen and Gale, 1994; Williamson, 1994), ambiguity aversion (Dow and Werlang, 2002; Cao, Wang and Zhang, 2005; Epstein and Schneider, 2007), disappointment aversion (Ang, Bekaert and Liu, 2005) and behavioral ones, based on, e.g., loss aversion (Gomes, 2005), influence of social interaction (Hong, Kubik, and Stein, 2004; Brown, Ivković, Smith, and Weisbenner, 2008). More specifically, our paper is related to Osili and Paulson (2008a,b) and Guiso, Sapienza and Zingales (2008) who, among others, relate institutional environment and social capital to stock market participation. Osili and Paulson (2008a,b) use data on immigrants to the US to investigate the

---

2 In short, the puzzle is that if the expected return on a stock exceeds the risk free rate, then, absent any frictions, everyone should participate in the stock market, albeit to varying degrees. However, we know that not all real-world investors participate in the stock market.

3 The literature in this area also includes, e.g., Guiso, Sapienza, and Zingales (2004), Georgarakos and Pasini (2011), Christelis, Georgarakos, and Haliassos (2013).
impact of institutions on households’ participation in financial markets. They find that the institutional quality of the country of origin has a large impact on a broad range of financial market behaviors, and that the effect of home country institutions is absorbed early in life. Guiso, Sapienza and Zingales (2008) investigate the effect of trust on stock market participation, and in their study of Dutch and Italian micro data, as well as cross-country data, lack of trust emerges as an important factor in explaining the stock market participation puzzle. In essence, we bring together and extend these papers. That is, compared to Osili and Paulson (2008a,b), we develop a model in which trust at the individual level is one of the key ingredients, and we make use of our data in this regard. Because our data set spans respondents in fourteen different countries, we are able to add the institutional quality of the country of residence into the analysis and we study the interaction between and the relative importance of the country of origin’s institutional quality, relative to that of the country of residence. Whereas Guiso, Sapienza and Zingales (2008) treat trust as exogenous, we analyze the formation of trust through learning in a repeated interaction model and investigate the impact of institutional quality on trust. We believe that our analysis allows for a better understanding of how the institutional quality of not only the country of origin, but also that of the country of residence affects stock market participation.

The remainder of our paper is organized as follows. Section 2 presents our theory, which models how institutional quality affects trust through learning and how trust in turn affects stock market participation. Section 3 presents our empirical model. Section 4 describes the data and in Section 5, we present our empirical results. Finally, Section 6 concludes the paper.
2. Theoretical motivation

Drawing on Guiso, Sapienza and Zingales (2008), we develop a framework for analyzing how trust is formed and how it affects stock market participation. The main difference between our model and the one proposed by Guiso, Sapienza and Zingales (2008) is that we specifically consider the formation of trust through learning.

There are two assets available for investment: one stock and one short term bond. The short term gross interest rate is $R_f$, where $R_f \geq 1$. If there is fraud, then the stock’s gross return is $\varepsilon$, where $\varepsilon > 0$ is close to zero, and certainly less than one. In the absence of fraud, the stock delivers a gross return $\tilde{R}_t^+ > \varepsilon$. We also assume that $E_t[\tilde{R}_{t+1}^+] > R_f$. Fraud occurs independently across periods. The probability of a fraud ($p$) can either be high ($p = p_h$) or low ($p = p_l$), where $p_h > p_l$, but this probability does not change over time.

Agents maximize their expected utility of final wealth by choosing the relative allocation of their wealth to the stock ($\alpha_t$). They have a short-selling constraint, meaning that $\alpha_t \geq 0$. For simplicity, we assume that agents have logarithmic utility. However, our main results regarding stock market participation also hold for myopic risk averse investors in general (given standard assumptions on the elementary utility function), as shown in Appendix A.1. Agents know the riskfree rate, the stock return if there is fraud and the distribution of the stock return if there is no fraud, but they do not know the probability of fraud. They update their probability of being in the state with a high probability of fraud using their historical observations on fraud in a Bayesian manner. Each agent has a prior regarding the probability

---

4 In Guiso, Sapienza and Zingales (2008), $\varepsilon$ is equal to zero. Because we assume logarithmic utility, we need to let $\varepsilon$ be greater than zero.

5 It is well-known that logarithmic utility induces myopic behavior (e.g., Mossin 1968, Hakansson 1971). This is important in this setting, because agents are learning about the probability of fraud, and thus, in general, the perceived investment opportunity set will change over time.
of fraud: the prior is that the probability of fraud is high with probability \( \theta_0 \) (for ease of exposition, we suppress an index indicating what agent this prior belongs to). Let \( D_t \) denote the number of frauds at time \( t \). By Bayes theorem, agents’ posterior probability of being in the state with a high probability of fraud is given by

\[
Prob(p = p_h|D_t = k) = \frac{\theta_0 \cdot \text{Prob}(D_t = k|p = p_h)}{\theta_0 \cdot \text{Prob}(D_t = k|p = p_h) + (1 - \theta_0) \cdot \text{Prob}(D_t = k|p = p_l)}
\]

\[
= \frac{\theta_0 \binom{t}{k} p_h^k (1 - p_h)^{t-k}}{\theta_0 \binom{t}{k} p_h^k (1 - p_h)^{t-k} + (1 - \theta_0) \binom{t}{k} p_l^k (1 - p_l)^{t-k}}
\]

At date \( t=T-1 \) (where \( T \) is the final date), the agents’ problem looks as follows (for ease of exposition, we suppress individual-specific indices):

\[
\max_{\alpha_{T-1} \geq 0} \text{Prob}(\bar{R}_T = \varepsilon|D_{T-1}) E_{T-1}[\ln \bar{W}_T|\bar{R}_T = \varepsilon] \\
+ \left(1 - \text{Prob}(\bar{R}_T = \varepsilon|D_{T-1})\right) E_{T-1}[\ln \bar{W}_T|\bar{R}_T > \varepsilon]
\]

s.t. \( \bar{W}_T = W_{T-1}[R_f + \alpha_{T-1}(\bar{R}_T - R_f)] \)

Inserting the wealth constraint into the objective function, we find that solving the above maximization problem is equivalent to finding a non-negative \( \alpha_{T-1} \) which maximizes the function

\[
f_{T-1}(\alpha_{T-1}) = \text{Prob}(\bar{R}_T = \varepsilon|D_{T-1}) \ln \left(R_f + \alpha_{T-1}(\varepsilon - R_f)\right) \\
+ \left(1 - \text{Prob}(\bar{R}_T = \varepsilon|D_{T-1})\right) E_{T-1}\left[\ln \left(R_f + \alpha_{T-1}(\bar{R}_T - R_f)\right)\right].
\]

We note that this function is strictly concave in \( \alpha_{T-1} \). Therefore, the agent will participate in the stock market (\( \alpha_{T-1} > 0 \)) if and only if \( f_{T-1}(0) > 0 \), or, equivalently, if and only if
We call \( \xi_t \equiv \frac{E_{T-1} \left[ \hat{R}^+_T - R_f \right]}{R_f - \varepsilon} \) the stock’s normalized conditional risk premium at time \( t \). By assumption, this is a strictly positive quantity. The interpretation of the condition in (4) is straightforward: in order for the agents to participate in the stock market, the total expected return on the stock needs to be greater than the risk free rate. Alternatively, we can say that the conditional expected return in the absence of fraud needs to be sufficiently large, or, the probability of fraud needs to be sufficiently small.

The problem clearly has a recursive structure. As we solve the maximization problem working backwards period-by-period until we reach time 0, the problem looks as follows at date \( t = T-q \).

\[
\max_{\alpha_{T-q} \geq 0} \text{Prob}(\hat{R}_{T-q+1} = \varepsilon | D_{T-q}) E_{T-q} \left[ \ln \hat{W}_T | \hat{R}_{T-q+1} = \varepsilon \right] + \left( 1 - \text{Prob}(\hat{R}_{T-q+1} = \varepsilon | D_{T-q}) \right) E_{T-q} \left[ \ln \hat{W}_T | \hat{R}_{T-q+1} > \varepsilon \right]
\]

s.t. \( \hat{W}_T = W_{T-q-1} [R_f + \alpha_{T-q} (\hat{R}_{T-q+1} - R_f)] \prod_{i=1}^{q-1} [R_f + \alpha^*_T (\hat{R}_{T-i+1} - R_f)] \)

where the \( \alpha^*_T \)’s are the optimal solutions from the previously solved problems.

Due to the additivity of the logarithmic function, solving the above maximization problem is equivalent to finding a non-negative \( \alpha_{T-q} \) which maximizes the function

\[
f_{T-q}(\alpha_{T-q}) = \text{Prob}(\hat{R}_{T-q+1} = \varepsilon | D_{T-q}) \ln \left( R_f + \alpha_{T-q} (\varepsilon - R_f) \right) + \left( 1 - \text{Prob}(\hat{R}_{T-q+1} = \varepsilon | D_{T-q}) \right) E_{T-q} \left[ \ln \left( R_f + \alpha_{T-q-1} (\hat{R}_{T-q+1} - R_f) \right) \right]
\]

Repeating the arguments above, the agent will participate in the stock market if and only if

\[
\xi_{T-q} \equiv \frac{E_{T-q} \left[ \hat{R}^+_T - R_f \right]}{R_f - \varepsilon} > \frac{\text{Prob}(\hat{R}_{T-q+1} = \varepsilon | D_{T-q})}{1 - \text{Prob}(\hat{R}_{T-q+1} = \varepsilon | D_{T-q})}, q = 1, 2, ..., T,
\]
meaning that, for time \( t=1,2,\ldots,T-1 \), the condition for stock market participation is given by

\[
\xi_t \equiv \frac{E_t[\tilde{R}_{t+1} - R_f]}{R_f - \epsilon} > \frac{\text{Prob}(\tilde{R}_{t+1} = \epsilon|D_t)}{1 - \text{Prob}(\tilde{R}_{t+1} = \epsilon|D_t)}
\]  

(8)

or, written differently,

\[
\text{Prob}(\tilde{R}_{t+1} = \epsilon|D_t) < \frac{\xi_t}{1+\xi_t}
\]  

(9)

The condition for stock market participation in (8) will also hold for any \textit{myopic} investor with a strictly increasing, strictly concave and twice-continuously differentiable elementary utility function \( u \) satisfying \( \lim_{W \to 0} u'(W) = +\infty \) (see Appendix A.1).

We can use the law of total probability to calculate the probability of fraud:

\[
\text{Prob}(\tilde{R}_{t+1} = \epsilon|D_t = k) = 
\]

\[
\text{Prob}(p = p_h|D_t = k) \cdot \text{Prob}(\tilde{R}_{t+1} = \epsilon|D_t = k, p = p_h) + 
\]

\[
+ \text{Prob}(p = p_l|D_t = k) \cdot \text{Prob}(\tilde{R}_{t+1} = \epsilon|D_t = k, p = p_l)
\]

\[
= \frac{\theta_0 p_h^{k+1}(1-p_h)^{t-k} + (1-\theta_0)p_l^{k+1}(1-p_l)^{t-k}}{\theta_0 p_h^k(1-p_h)^{t-k} + (1-\theta_0)p_l^k(1-p_l)^{t-k}}
\]  

(10)

We note that this probability is between \( p_l \) and \( p_h \). By the above equation, the condition for stock market participation in (8) can be rewritten as

\[
\xi_t > \frac{\theta_0 p_h^{k+1}(1-p_h)^{t-k} + (1-\theta_0)p_l^{k+1}(1-p_l)^{t-k}}{\theta_0 p_h^k(1-p_h)^{t-k+1} + (1-\theta_0)p_l^k(1-p_l)^{t-k+1}}
\]  

(11)

The boundary for the normalized risk premium to be participation-inducing is increasing in the prior \( \theta_0 \), because, as can be seen from dividing through by \( \theta_0 \) both in the numerator and

\[\footnote{Notice that \( \text{Prob}(\tilde{R}_{t+1} = \epsilon|D_t = k, p = p_h) = p_h \) and \( \text{Prob}(\tilde{R}_{t+1} = \epsilon|D_t = k, p = p_l) = p_l \).} \]
the denominator of the right-hand side of (11), and taking the derivative with respect to $1/\theta_0$, we have that this is given by

$$
\frac{p_l^k (1 - p_l)^{-k} p_h^k (1 - p_h)^{-k} (p_l - p_h)}{(p_h^k (1 - p_h)^{-k+1} - p_l^k (1 - p_l)^{-k+1} + \frac{1}{\theta_0} p_l^k (1 - p_l)^{-k+1})^2} < 0.
$$

(12)

Thus, if the prior probability of the state with high probability of fraud increases, the expected return on the stock in the absence of fraud needs to be higher in order for the agent to participate in the stock market. As summarized in the following lemma, we can also show that, if the normalized risk premium ($\xi_t$) lies between $p_l/(1 - p_l)$ and $p_h/(1 - p_h)$, then the prior probability required to induce stock market participation is lower the larger the number of observed frauds ($k$). The interpretation of the bounds on the normalized risk premium is that in order for it to be possible to satisfy (11) with a lower prior, $\xi_t$ has to be greater than $p_l/(1 - p_l)$, which is the lowest possible value on the right-hand side limit in (11). Moreover, if $\xi_t > p_h/(1 - p_h)$, then all priors $\theta_0 \in [0,1]$ will induce participation, because $p_h/(1 - p_h)$ is the highest possible value on the right-hand side limit in (11). 

**Lemma 1:** Suppose $\frac{p_l}{1 - p_l} < \xi_t < \frac{p_h}{1 - p_h}$. Then, the prior probability ($\theta_0$) required for stock market participation is decreasing in the number of observed frauds ($k$).

**Proof:** By inverting the requirement for stock market participation in (11), we get

$$
\theta_0 \leq \frac{p_l^k (1 - p_l)^{-k} [(1 - p_l)\xi_t - p_l]}{p_l^k (1 - p_l)^{-k} [(1 - p_l)\xi_t - p_l] + p_h^k (1 - p_h)^{-k} [p_h - (1 - p_h)\xi_t]}.
$$

(13)

Dividing both the numerator and the denominator by $p_l^k (1 - p_l)^{-k}$, we get to

---

7 If $\xi_t = p_h/(1 - p_h)$, then all priors except $\theta_0 = 1$ will induce participation.
\[ \theta_0 < \frac{(1 - p_l) \xi_t - p_l}{[(1 - p_l) \xi_t - p_l] + (p_h(1 - p_l))^{\kappa} \left( \frac{1 - p_h}{1 - p_l} \right)^t [p_h - (1 - p_h) \xi_t]} . \quad (14) \]

We note that denominator in the right-hand side limit is increasing in \( k \), meaning that the limit is decreasing in \( k \), which in turn implies that the \( \theta_0 \) required for stock market participation is decreasing in the number of observed frauds (\( k \)).

Now, consider two countries: country \( H \) and country \( L \). Country \( H \) is a country with high institutional quality, and so in that country, the true probability of fraud is \( p^H = p_l \) (but this is unknown to the investors) whereas country \( L \) is a country with low institutional quality and the true probability of fraud is \( p^L = p_h \). Each country has a continuum of investors with a positive mass and with identical distributions of priors in the interval \([0,1]\), with positive support for the entire interval. Investors can only invest in their country of residence, and the return distributions in the absence of fraud are identical, as are the interest rates.

Provided that \( \xi_t > p_l/(1 - p_l) \) and \( \xi_t < p_h/(1 - p_h) \), so that, if agents learn the true probability of fraud, no one in country \( L \) will invest in the stock, whereas everyone in country \( H \) will invest in the stock, we generally expect to see a higher degree of stock market participation in country \( H \) than in country \( L \). In fact, as \( t \) increases, the probability that the citizens of country \( L \) have experienced more frauds than the citizens of country \( H \) increases as well. For large \( t \), the number of frauds, which follows a binomial distribution, can be approximated by a normal distribution:

\[ (D_t^H | p^H = p_l) \sim N(tp_l, tp_l(1 - p_l)) \quad (15) \]

\[ (D_t^L | p^L = p_h) \sim N(tp_h, tp_h(1 - p_h)) \quad (16) \]

Hence, provided that the number of frauds in country \( H \) and the number of frauds in country \( L \) are independent, then, for large \( t \), the probability that the citizens of country \( L \) have experienced more frauds than the citizens of country \( H \) is given by
\[
\text{Prob}(D_t^L > D_t^H | p^L = p_h, p^H = p_t) = \Phi \left( \frac{(p_h - p_t)\sqrt{t}}{\sqrt{p_h(1-p_h) + p_t(1-p_t)}} \right),
\]

(17)

where \( \Phi(.) \) is the cdf of a standard normal. Since \( p_h > p_t \), the above probability will approach one as \( t \) gets larger. By Lemma 1, this means that the participation-inducing value of the prior probability of the state with a high probability of fraud is lower in country \( L \) than in country \( H \) with that same probability. In turn, this implies that, as \( t \) gets larger, the probability that the fraction participating in the stock market is higher in country \( H \) than in country \( L \) also approaches one. Guided by the above reasoning, we formulate the following hypothesis.

**Hypothesis 1:** In countries with better institutional quality, people tend to have a higher level of trust, which in turn induces a higher degree of stock market participation in those countries.

Next, we compare the stock market participation between immigrants migrating from country \( L \) to country \( H \) and natives in country \( H \). Here, we make the behavioral assumption that immigrants use a weighted average of beliefs,

\[
\text{Prob}^I (\tilde{R}_{t+1} = \varepsilon | D^L_t, D^H_t) = w(E) \text{Prob} (\tilde{R}_{t+1} = \varepsilon | D^H_t) + (1 - w(E)) \text{Prob} (\tilde{R}_{t+1} = \varepsilon | D^L_t),
\]

(18)

where \( E \) is the level of education. The higher the level of education \( (E) \), the higher the weight assigned to the belief that is relevant for their new country of residence. The weighting of beliefs is thought to capture the phenomenon that immigrants’ beliefs are affected by what happens and has happened in their home country, and more so if the level of education is lower: a well-educated immigrant forms his/her beliefs based on the history of events for the new country of residence to a larger extent. Of course, the weight \( w(E) \) needs to be between zero and one. We let \( w'(E) > 0 \) for \( 0 \leq E < E_{\text{max}} \), \( w(0) = 0 \), \( w(E_{\text{max}}) = 1 \), where \( E_{\text{max}} \) is the maximum level of education.
As $t$ increases in (16), the probability that $D_t^L > D_t^H$ approaches one. Therefore, we assume that $D_t^L > D_t^H$ in the following. It then follows that the probability that our conclusions will hold approaches one as $t$ increases.

If we compare immigrants with lower education than the maximum level $E_{max}$ to natives and assume that the two groups have identical distributions of priors with positive support on $[0,1]$, we can conclude that a higher fraction of natives will invest in the stock market (provided that $p_t/(1-p_t) < \xi_t < p_h/(1-p_h)$).

Next, let us consider the effect of education on immigrants’ stock market participation. Using a similar reasoning as in Lemma 1, we can establish that the highest participation-inducing prior belief is decreasing in the level of education (again provided that $p_t/(1-p_t) < \xi_t < p_h/(1-p_h)$).

**Lemma 2:** The rational probability of fraud given the number of observed frauds (see equation (9)) is increasing in the number of observed frauds.

**Proof:** We can rewrite equation (10) as

$$Prob\left(\bar{R}_{t+1} = \epsilon \mid D_t = k\right) = \frac{ap_h+bpf(k)}{a+bf(k)},$$

where $a = \theta_0(1-p_h)^t$, $b = (1-\theta_0)(1-p_h)^t$, and

$$f(k) = \left(\frac{p_t(1-p_h)}{(1-p_t)p_h}\right)^k.$$

Since $p_h > p_t$, we have that $f'(k) < 0$. Now, consider how the probability in (19) changes as we increase the number of observed frauds:

$$\frac{\partial Prob(\bar{R}_{t+1} = \epsilon \mid D_t = k)}{\partial k} = \frac{ba(1-p_t)^t}{(a+bf(k))^2} f'(k) > 0.$$  

**Lemma 3:** Suppose $D_t^L > D_t^H$. Then, the prior probability ($\theta_0$) required in order to reach a certain probability of fraud is increasing in the level of education ($E$).
**Proof:** Here, we make use of the law of total differentiation, holding \( \text{Prob}(\tilde{R}_{t+1} = \varepsilon | D_t^H, D_t^L) \) constant:

\[
0 = d\text{Prob}(\tilde{R}_{t+1} = \varepsilon | D_t^H) = w'(E) \left( \text{Prob}(\tilde{R}_{t+1} = \varepsilon | D_t^H) - \text{Prob}(\tilde{R}_{t+1} = \varepsilon | D_t^L) \right)
\]

\[
= dE \left[ w(E) \frac{\partial \text{Prob}(\tilde{R}_{t+1} = \varepsilon | D_t^H)}{\partial \theta_0} + (1 - w(E)) \frac{\partial \text{Prob}(\tilde{R}_{t+1} = \varepsilon | D_t^L)}{\partial \theta_0} \right] d\theta_0.
\]

(22)

Hence, we have that

\[
\frac{d\theta_0}{dE} = - \frac{w'(E) \left[ \text{Prob}(\tilde{R}_{t+1} = \varepsilon | D_t^H) - \text{Prob}(\tilde{R}_{t+1} = \varepsilon | D_t^L) \right]}{w(E) \frac{\partial \text{Prob}(\tilde{R}_{t+1} = \varepsilon | D_t^H)}{\partial \theta_0} + (1 - w(E)) \frac{\partial \text{Prob}(\tilde{R}_{t+1} = \varepsilon | D_t^L)}{\partial \theta_0}} > 0, \ E \in [0, E_{\text{max}}),
\]

(23)

where the inequality is due to \( w'(E) > 0, \ \frac{\partial \text{Prob}(\tilde{R}_{t+1} = \varepsilon | D_t^j)}{\partial \theta_0} > 0 \) \((j = H, L)\) and, by Lemma 2,

\( \text{Prob}(\tilde{R}_{t+1} = \varepsilon | D_t^H) < \text{Prob}(\tilde{R}_{t+1} = \varepsilon | D_t^L) \) because \( D_t^H < D_t^L \).

The interpretation of Lemma 3 is that as education increases, a higher prior (\( \theta_0 \)) is needed to reach the lowest probability of fraud required for nonparticipation in the stock market. Now, consider a continuum of immigrants having a certain distribution of priors with positive support on \([0,1]\) and suppose that \( p_l / (1 - p_l) < \xi_t < p_h / (1 - p_h) \). If we increase the level of education \( E \), while holding everything else constant (including the distribution of priors), the prior needed to induce nonparticipation increases. That is, the higher the education of the immigrants, the higher the fraction of immigrants participating in the stock market. This leads us to formulate the following hypothesis.

**Hypothesis 2:** Immigrants who emigrate from a country of lower institutional quality tend to have lower trust, which in turn means that they tend to be less prone to participate in the stock market. This effect is more pronounced the lower the education of the immigrants, and the lower the institutional quality of their country of origin.
In Appendix A.2, we consider the effect of adding a fixed participation cost. This introduces interactions between wealth and trust. First, given that the investor would invest if there were no participation costs, there is a threshold level of wealth below which the investor would not participate. Second, this threshold level of wealth is increasing in the prior probability of fraud. Third, adding a participation cost lowers the prior probability of fraud that triggers nonparticipation.

### 3. Institutional quality, learning and participation

Based on our theoretical hypotheses, we construct an empirical model that investigates the degree to which stock market participation is affected by households’ level of trust related to institutional quality. Our empirical model consists of two sequential parts. In the first part, we examine how institutional quality affects trust and, in the second part, we investigate the degree to which the level of trust that is explained by institutional quality affects stock market participation.

The first part of the empirical model defines the following relationship:

\[ T_i^* = \text{func}(X_i) + \epsilon_i \]

where \( T_i^* \) is the latent level of trust for individual \( i \), \( X_i \) is the level of institutional quality experienced by individual \( i \), and \( \epsilon_i \) is an error term.

Since immigrants may have been exposed to completely different institutional conditions in their country of origin compared to the country of residence, we allow immigrants’ level of trust to depend on a weighted average of institutional qualities in their country of residence and country of origin. In our baseline model, equation (24) is specified as

\[ T_i^* = b_N D_{N,i} X_i^{res} + b_I D_{I,i} \left( w X_i^{res} + (1 - w) X_i^{ori} \right) + \epsilon_i, \]

where \( X_i^{res} \) is the institutional quality of the country of residence for individual \( i \), \( X_i^{ori} \) is the
institutional quality of the country of origin for immigrant \(i\), \(D_{N,i}\) is a dummy variable for natives, and \(D_{I,i}\) is a dummy variable for immigrants. Further, \(w \in [0,1]\) is the weight of the institutional quality of the immigrants’ country of residence. In the baseline model, \(w\) is assumed to be constant. \(T^*\) is an unobservable continuous latent variable. What we can observe is a discrete ordinal variable of trust, \(T\), extracted from the survey data SHARE. We use ordered probit to estimate (25).

As hypothesized in Section 2, immigrants’ degree of adaptation to the new institutional environment is related to their level of education. It seems plausible that immigrants with a higher level of education would learn the institutional quality of their new country of residence faster. To capture this learning process, we extend the model above and define the weight \(w\) for each immigrant as a (logistic) function of his or her level of education:

\[
T_i^* = b_N D_{N,i} x_{i}^{res} + b_I D_{I,i} x_{i}^{ori} + b_I w_i D_{I,i} (x_{i}^{res} - x_{i}^{ori}) + \varepsilon_i, \tag{26}
\]

\[
w_i = \frac{1}{1 + \exp(-\gamma (E_i - c))},
\]

where \(E\) is the number of years spent on education, \(c\) is the inflection point of the curve and \(\gamma\) determines the shape of the curve (a small value corresponds to relatively smooth changes in function values). Such specification for \(w\) assures that the value of \(w\) is in the interval \([0, 1]\).

We use the estimated parameters obtained from the ordered probit estimation of equation (26) to decompose trust for individual \(i\) into two parts: one that is explained by institutional quality and one that is not explained by institutional quality and may depend on other social factors and/or individual attributes.

\[
T_{i}^{expl} = E[T_i|X_i^T] = \sum_{j=1}^{J} \text{Prob}[T_i = j|X_i^T] \times j, \tag{27}
\]

\[
T_{i}^{unexpl} = T_i - E[T_i|X_i^T],
\]

where \(j = 0, 1, ..., 10\), since \(T\) scales from 0 (low trust) to 10 (high trust). \(X_i^T\) consists of all
the explanatory variables for individual \(i\) in equation (26). \(Prob[T_i = j|X_i^T]\) is the implied probability that the level of trust of individual \(i\) is equal to \(j\), conditional on \(X_i^T\). See equation (B1) in Appendix B for a calculation of \(Prob[T_i = j|X_i^T]\).

The second part of the analysis relates stock market participation to the explained and the unexplained parts of trust. The dependent variable, stock market participation, is binary and coded as one if the household owns stocks and zero otherwise. The regression for the latent variable \(y_i^*\), determining the stock market participation of individual \(i\), is specified as

\[
y_i^* = a_0 + a_1 T_i^{expl} + a_2 T_i^{unexpl} + \sum_{k=2}^{K} a_{k+1} Z_{k_i} + u_i, \tag{28}
\]

where \(Z_{k_i}\) is control variable \(k\) for individual \(i\).

The marginal effect of the explanatory variables of the probit model in equation (28) is computed in the conventional way. However, we need to use the chain rule to compute the marginal effects of the variables included in equation (26) for trust, i.e. institutional quality of country of origin and country of residence, and education, on stock market participation.

4. Data

The paper is based on micro level data on individual/household characteristics and portfolio composition. The main source is the Survey of Health, Aging and Retirement in Europe (SHARE). SHARE includes comparable household-level data for people aged 50 and above in 14 European countries: Austria, Belgium, Czech Republic, Denmark, France, Germany, Greece, Ireland, Italy, Poland, the Netherlands, Spain, Sweden, and Switzerland. SHARE contains detailed information on stock market participation, wealth, income, employment, immigration background, and other demographic characteristics. The advantage of using survey data as compared to actual micro data collected by statistical bureaus is that, due to the circumstance that the questionnaire is fixed, it facilitates cross-country comparisons. More
importantly, as opposed to micro data, the surveys contain information about individuals’ self-assessed (subjective) degree of risk aversion and trust in other people.

In the empirical estimation, we use stock market participation (i.e. stock ownership), wealth, and income of household, while household level of trust, risk aversion, and demographic attributes are assumed to be those of the household head. To select the decision maker for households with more than one possible decision maker, we first use the variable income, and the person with the higher income in the household is selected as the decision maker. For households that do not report their income, we use the person with the higher education in the household as the decision maker. If neither income nor education is reported, we pick the man as the decision maker.

In the first part of the estimation, level of trust is an ordinal variable (from 0 to 10) extracted from individual answers to the following question in SHARE:

“Generally speaking, would you say that most people can be trusted or that you can't be too careful in dealing with people?”,

where 0 means that the interviewee can't be too careful and 10 means that most people can be trusted. For institutional quality in different countries, we use the index “Rule of law”\(^8\) collected from World Bank, which “reflects perceptions of the extent to which agents have confidence in and abide by the rules of society, and in particular the quality of contract enforcement, property rights, the police, and the courts, as well as the likelihood of crime and violence.” Panel A of Table 1 presents summary statistics for trust and institutional quality. We can see that the variations in individual trust and countries’ institutional quality are reasonably large in our sample. The institutional quality of immigrants’ country of origin has a larger variation than the institutional quality of the fourteen European countries. Also, the

\(^8\) For the sake of robustness, we also use the index of legal system and property rights protection from Fraser Institute as our measure of institutional quality. Our empirical results continue to hold.
mean of the institutional quality of the country of origin is considerably lower than that of the institutional quality of the country of residence, which reflects that most (73%) immigrants in our sample emigrated from a country with lower institutional quality.

[Insert Table 1]

Panel B of Table 1 presents summary statistics for the variables used in the second part of the empirical estimation. Stock market participation is a binary variable that is equal to one if the household owns stocks and zero otherwise. The variable of risk aversion is equal to 1 if the interviewee is willing to take substantial financial risks expecting to earn substantial returns, equal to 2 if the interviewee willing to take above average financial risks expecting to earn above average returns, equal to 3 if the interviewee is willing to take average financial risks expecting to earn average returns, and equal to 4 if the interviewee not willing to take any financial risks.

In addition, we show for each country its institutional quality and the average institutional quality of its immigrants’ country of origin (see Figure 1). There is a considerable difference between the two series for most of the countries. For all countries except Poland, immigration tends to be from countries with lower institutional quality. The reverse pattern in Poland depends mainly on its low institutional quality rather than the higher institutional quality of the immigrants’ country of origin. Figure 2 shows the average values of trust, presenting averages separately for natives and immigrants in each country. As seen in the figure, there are no considerable differences between average values of trust of natives as compared to immigrants. Further, Denmark has the largest mean value, followed by Sweden, Switzerland, Netherlands, and Ireland, while residents in France and Italy seem to be the most skeptical groups in our sample. We also show the rate of stock market participation in different countries (see Figure 3). The participation rate varies largely across countries. The participation rate among natives is considerably higher in Denmark and Sweden (over 35%).
than in the other countries. Sweden also has the largest rate of stock market participation among immigrants (over 25%). Poland and the Czech Republic have the lowest participation rates (1% and 2%, respectively) among natives. In our sample, the immigrants in Austria, Czech Republic, Greece and Poland do not own stocks.

[Insert Figure 1- Figure 3]

5. Results

In this section, we present our empirical results. We follow a two-step estimation procedure. In the first step, we estimate a relation between trust and institutional quality, and in the second step, we consider the relation between stock market participation and the explained and unexplained parts of trust from the first regression. Our results confirm our hypotheses: institutional quality has a significant effect on trust, and trust—particularly the part of trust that is explained by institutional quality—in turn has a significant effect on stock market participation. We also find that the more highly educated immigrants’ trust is to a larger extent influenced by the institutional quality of their new country of residence. This is in line with the notion that more highly educated immigrants need to exert less effort in order to adapt to the institutional quality of their new country of residence.

5.1 The effect of institutional quality on trust

We start by analyzing the impact of institutional quality on households’ level of trust, by estimating the ordered probit models in (25) and (26) with the standard maximum likelihood procedure. The related likelihood functions are maximized using the simulated annealing algorithm (see Goffe et al. 1994), which is very robust and seldom fails to reach the global optimum, even for very complicated problems. Table 2 reports the estimates. The first column displays the estimates of the baseline model in (25). $b_N$ and $b_I$ are positive and highly statistically significant, implying that better institutions make both natives and immigrants
more trustful. For immigrants, \( w \), the weight of the institutional quality of the country of residence is equal to 83.4% and significantly different from zero, indicating that the institutional quality of the country of residence plays a significant role in forming immigrants’ beliefs. Furthermore, we test the null hypothesis: \( w = 1 \) against the one-sided alternative \( w < 1 \). The null hypothesis is rejected with a p-value of 1.7%. This test result indicates that people who have experienced a sudden change in institutional environment due to immigration do not fully adopt a level of trust that is consistent with the institutional quality of their new country of residence: the institutional quality of their country of origin still influences their beliefs. This is consistent with the finding in Osili and Paulson (2008b) that the impact of home-country institutions is persistent and absorbed early in life. However, we also find that the institutional quality of the country of residence is more influential on average: a one-tailed test shows that \( \hat{w} \) is larger than 0.5 at the 1% significance level.

[Insert Table 2]

The model in (25) restricts the coefficients of both of the institutional quality variables for immigrants to have the same sign. For robustness, we run an ordered probit regression without any restriction on immigrants’ response to the institutional quality of the country of residence and the institutional quality of the country of origin:

\[
T_i^* = b_0 + b_N D_{N,i} X_{i}^{res} + b_i^{ori} D_{i,i} X_{i}^{ori} + b_i^{res} D_{i,i} X_{i}^{res} + \varepsilon_i. \tag{29}
\]

The second column in Table 2 reports the estimates. The parameter \( b_N \) denotes the response of the trust level of a native resident to changes in the institutional quality of the country of residence, \( b_i^{ori} \) is the response of the trust level of an immigrant to the institutional quality in the country of origin, and \( b_i^{res} \) is the response of the trust level of an immigrant to the institutional quality in the country of residence. We can see that the results from the unrestricted regression agree with those from the model in (25): the effects of institutional
quality are positive and significant. For people who have emigrated, the institutional qualities of both the country of residence and the country of origin have significant impact on trust. However, the institutional quality of the country of residence is more influential than that of the country of origin.

In the last column, we show the role of education in the learning process of people who have experienced a sudden change in institutions due to immigration. We use the extended model in (26), where the weight of the institutional quality of the country of residence depends on immigrants’ level of education. The fact that $\gamma$ is positive and highly significant indicates a positive relationship between education and the weight assigned to the institutional quality of immigrants’ country of residence. Based on our estimates, we show the relationship between the weight and education graphically in Figure 4. The figure shows remarkable differences in the degree of adaptation to the new institutional environment between immigrants with lower education and those with higher education. Immigrants with no education have very low degrees of adaptation, with the weight of the institutional quality of the country of residence, $(\tilde{w})$ having a value of around 25%. The degree of adaptation increases sharply with education for low-educated immigrants and $\tilde{w}$ turns larger than 50% when the level of education reaches the inflection point $\hat{c}$, 4.5 years. At the mean level of education, about 11 years education, $\tilde{w}$ is above 85%. Thus, the trust of highly-educated people responds almost exclusively to the institutional quality of the country of residence.

[Insert Figure 4]

5.2 Institutional quality, trust and stock market participation

In this section, we examine the effect of institutional quality on stock market participation through the belief-forming process. We start by estimating four specifications of the probit model for stock market participation, of which the specification described in equation (28) is our main interest. Table 3 presents the estimation results. The first column of Table 3 shows
the results for model 1 (M1), where the explanatory variable is the self-assessed level of trust extracted from the SHARE survey data. The coefficient associated with the trust variable is positive and highly significant, indicating that people with higher trust levels are more likely to participate in the stock market. In model 2 (M2), we regress stock market participation on the decomposed parts of trust: one that is explained by institutional quality and one that is not explained by institutional quality. We calculate these two parts using the relations in equation (27). The second column of Table 3 shows that both the explained and the unexplained parts of trust have positive and highly significant effects on stock market participation. Furthermore, judging from the Akaike and Bayesian information criteria, M2 remarkably improves upon M1 by taking into account the role of institutions in the belief-forming process. Then, we extend M1 to M3 by controlling for a variety of individual characteristics that have been shown to affect stock market participation in previous studies. The third column shows that the coefficient related to the self-assessed level of trust remains highly significant. Similarly, we extend M2 to M4, described in equation (28). We report the coefficients and average marginal effects of the explanatory variables across observations in M4 in columns four and five. We see that the effects of the explained and unexplained parts of trust remain robust to the inclusion of various control variables. To facilitate a comparison between the effect of the explained part of trust and that of the unexplained part, we calculate their marginal effects at their standardized values in the last column, where we standardize so that both variables have zero mean and unit variance. We find that the part of trust that is explained by institutional quality has a much higher impact on stock market participation than the unexplained part of trust.

---

9 Another common approach for estimating marginal effects in binary choice models is to calculate marginal effects at the sample means of the explanatory variables. The estimates of marginal effects given by this approach are thus conditional effects for an average person. Verlinda (2006) compares the two common approaches and concludes that averaging over the values of the marginal effects across observations should be the approach taken if one desires to purge the marginal effect of the explanatory variable and show the average effect in the population.
For the most part, the control variables display the expected signs. Income, wealth, years of education, gender (male), and the status of being married are all positively related to participation, while risk aversion affects participation negatively. Standard theory suggests that, in general, risk aversion is dependent on wealth, and intuitively, it ought to be a decreasing function of wealth. Since the coefficients related to these variables are both significant, we conclude that wealth affects participation not only through its effect on risk aversion. This might be considered as support for our theoretical results regarding wealth effects induced by participation costs (see Appendix A.2). The effect of year of birth is only significant for the specification with the trust variable from the survey, i.e., for M3.

Now, we connect the results from Tables 2 and 3 in order to study the effect of institutional quality on stock market participation. Based on the estimates of equations (26) and (28), we calculate the marginal effects of institutional quality on the probability of participating in the stock market (see equations B3-B12 in Appendix B) and the implied probabilities of participating given the estimates of our model (see equation B2 in Appendix B). Table 4 reports the average marginal effects, the average implied probability across observations and the actual participation rate in the sample. It shows that a unit increase in institutional quality increases a native household’s probability of investing in stocks by around 16 percentage points on average. This increase can be viewed as large, considering that both the actual and the average implied participation rates among the natives are around 15%. Further, a unit increase in the institutional quality of the country of residence leads to an increase in the participation probability among immigrants by about 9 percentage points on average. This is also economically significant, in relation to the actual participation rate (11.09%) and the average implied probability (10.34%) among immigrants, though less remarkable than the increase for natives. In comparison, a unit increase in the institutional quality of the country of
origin will only lead to a 1.25 percentage increase in the probability of stock market participation. Thus, it appears that increases in institutional quality have a larger effect on natives’ stock market participation than that of immigrants. Most likely, this result reflects the circumstance that for immigrants, there are other important determinants of stock market participation, besides institutional quality. For immigrants, the institutional quality of the country of residence appears to influence the likelihood of stock market participation to a larger degree than that of the country of origin. This reflects the finding in Section 5.1 that immigrants’ beliefs are influenced more by the institutional quality of the country of residence. Additionally, the actual participation rate and the average implied probability show that the native-borns are more likely to participate in stock markets than immigrants. This can be explained by the fact that most (about 73%) of the immigrants in our sample have emigrated from a country with lower institutional quality.

[Insert Table 4]

We further illustrate the relation between the probability of stock market participation and institutional quality in Figures 5-7. Figure 5 shows the average implied probability of stock market participation among natives in each country. We can clearly see that in countries with good institutions such as Denmark, Sweden and Switzerland, the implied probabilities of stock market participation are also high, and the opposite is true for countries with lower institutional qualities, such as Poland and Italy, and the Czech Republic. The implied probabilities are in line with the actual stock market participation rates shown in Figure 3. The exception is Austria, which has one of the highest institutional qualities but an average implied probability of participation (around 14%), below the cross-country mean. This can be explained by a variety of individual characteristics that we control for in our model. Nevertheless, our estimated implied probability is still higher than the actual participation rate in Austria (of around 6%). This calls for controlling for other country-level variables that may
affect stock market participation, which we will implement later in the paper.

[Insert Figure 5-7]

We show the implied probability of all immigrants in our sample in Figure 6. We can see that the implied probability increases both with the institutional quality of the country of residence and that of the country of origin. Furthermore, it is interesting to predict the probability that an average immigrant (i.e. an immigrant with average individual characteristics among immigrants) participates in the stock market after emigrating from his or her home country to another country. Hence, in Figure 7, we show the implied probability that an average immigrant participates in the stock market as a function of the institutional quality in the country of origin and that of the country of residence. For example, the participation probability for an average immigrant that has emigrated from Turkey (with an institutional quality value of around 0.13) to Italy (with an institutional quality value of around 0.58) is about 0.1%. The probability would have been 7.25% had he or she emigrated to Denmark (with an institutional quality value of about 1.95). In addition, we see from the figure that the probability that an average immigrant (with 11 years education) participates increases faster with the institutional quality of the country of residence than with that of the country of origin.

Furthermore, we investigate the role of education in determining a households’ likelihood of owning stocks. According to our model, education affects participation through two channels: the first one being that people with higher education tend to be more financially sophisticated and thus are more likely to own risky assets. This direct effect is captured by including education as a control variable in equation (28). The other channel, which pertains to people who have emigrated, is that education affects participation indirectly through its effect on the degree of adaptation to the new institutional environment. The last row of Table 4 shows the indirect effects of education on stock market participation, calculated as described in equation
(B13) in Appendix B. A one year increase in education will indirectly increase the probability of participation by 0.14 percentage points, as compared to the direct effect, which results in a 0.8 percentage point increase. That is, although the indirect effect is not the most important one, it is by no means negligible.

Education facilitates adaptation to new institutional environments, which in turn affects stock market participation. Figure 8 shows the marginal effect of institutional quality on participation at different levels of education (from no education to 25 years of education). As expected, the impact of the institutional quality of the country of residence increases with education. However, the impact of the institutional quality of the country of origin decreases with higher education after the time spent on education has reached five years. This can be explained by the fact that education also has a direct effect on participation, which is captured by including it as a control variable. For households with very low education, participation is influenced to a large extent by experiences in the home country. The effect of the institutional quality of the country of residence surpasses that of the home country if the household head has five or more years of education. Furthermore, the institutional quality of the country of origin has only a negligible effect on the participation of the most highly-educated immigrants, which is in line with the notion that for the most highly-educated immigrants, adaptation requires much less effort.

[Insert Figure 8]

The strong effect of institutional quality on participation through the variable explained trust, may to some extent be related to other country specific characteristics that are correlated with the countries’ institutional quality and are important for participation. In order to examine the robustness of our results in this regard, we use two country level control variables, i.e., gross national income (GNI) per capita and the ratio of total market capitalization (MCAP) to gross

---

10 The values of all variables but education are fixed. The values of the binary variables, married and male, are fixed at 0, while the values of others are fixed at the sample means.

11 In equation (B13), education enters in \( w_i \) as well as in \( f(\alpha'x_i) \).
domestic product (GDP). The former variable is supposed to control for the effect of countries’ general level of development, whereas the latter variable is thought to capture the impact of the countries’ stock market development. These variables are included one at a time into the regression equation M3 for stock market participation. The results are reported in Table 5. Panel A of the table shows that the coefficient associated with explained trust is very robust to the inclusion of GNI; it remains highly significant. The other coefficients’ significance levels also remain unchanged. The coefficient to GNI is not significant for the native-borns. For immigrants, the coefficient related to the GNI of the country of origin is significant and positive. That is, coming from a country with higher GNI results in increased participation, suggesting that there might be other important factors, like familiarity with the stock market, which can affect the degree of stock market participation for this group. However, the coefficient for the GNI of immigrants’ country of residence is negative and significant. The unexpected sign may be due to the correlation between GNI and the part of trust explained by institutional quality. If we eliminate the explained part of trust from the model, the coefficients related to all the GNI become positive and significant (see the second column of Table 5). These results indicate that GNI of the country of residence increases stock market participation because this variable to some extent represents institutional quality. This effect is removed when we add the institutional quality through the variable explained trust in to the regression.

Panel B of Table 5 gives the results for the augmented model M3, in which we include the ratio of stock market capitalization to GDP. The coefficient related to explained trust is still very robust to the inclusion of MCAP/GDP, while the effect of MCAP/GDP is insignificant for both immigrants and natives. If we exclude the variable explained trust from the regression, we find that the degree of development of the stock market of the country of
residence becomes significant, while that of the country of origin remains insignificant. The results above confirm that the coefficient associated with trust related to institutional quality is robust to the inclusion of GNI and MCAP/GDP, and that the importance of these control variables for participation can –to a sufficiently large degree– be captured by our measure of institutional quality.

6. Conclusion

In this paper, we analyze the effects of institutional quality on stock market participation, both theoretically and empirically. In our theoretical motivation, institutional quality affects trust through learning. We model agents as Bayesian updaters who from time to time observe frauds. In the model, higher institutional quality is likely to lead to a higher level of trust, and for a sufficiently high level of trust, agents want to invest in the stock market. Immigrants who emigrate from a country of lower institutional quality tend to exhibit lower levels of trust, which in turn means that they tend to be less prone to participate in the stock market. This effect is more pronounced the lower the education of the immigrants, and the lower the institutional quality of their country of origin.

In accordance with our theoretical motivation, we construct an empirical model to investigate the degree to which stock market participation is affected by households’ level of trust, which in turn is affected by institutional quality. Using European survey data (the SHARE data set), covering more than 30,000 individuals in fourteen European countries, and a measure of institutional quality from the World Bank, we find strong support for our hypotheses: institutional quality has a significant effect on individuals’ level of trust and trust (especially the part that is explained by institutional quality) in turn significantly affects the probability of stock market participation. In addition, we find that immigrants are affected not only by the institutional quality of their country of residence, but also by that of their country of origin.
However, on average, the former is more influential than the latter. The more time the immigrants have spent on education, the larger is the impact of the institutional quality of the country of residence. This result is in line with the notion that highly educated immigrants need to exert less effort in order to learn about their new institutional environment.
References

Table 1 Summary statistics

The table shows summary statistics of the variables we use. Panel A and Panel B present the variables we used in the first and the second parts of the estimation, respectively. All variables except institutional quality are from the Survey Health, Ageing, and Retirement in Europe. *Trust* is an index variable (from 0 to 10); an answer to the question “Generally speaking, would you say that most people can be trusted or that you can't be too careful in dealing with people?”, where 0 means the household head can't be too careful and 10 means that most people can be trusted by the household head. *Participation* is a binary variable, equal to one if the household owns stocks and zero otherwise. *Risk aversion* is elicited from answers to a question regarding the amount of financial risk that the household head is willing to take. It is equal to 1 if the household head is willing to take substantial financial risks expecting to earn substantial returns, equal to 2 if the household head willing to take above average financial risks expecting to earn above average returns, equal to 3 if the household head willing to take average financial risks expecting to earn average returns, and equal to 4 if the household head not willing to take any financial risks. *Institutional quality* is the Rule of law variable collected from the World Bank.

Table 2 The effect of institutional quality on trust

The table shows the results for ordered probit regressions of trust at the individual level on institutional quality at the country level (i.e. the Rule of law variable from the World Bank). The first column shows the estimates of equation (25). $b_I$ is the response of the trust level of an immigrant to the weighted average of institutional quality in the country of residence and institutional quality in the country of origin, $w$ is the weight assigned to country of residence. The second column shows the estimates for equation (29). $b_N$ is the response of the trust level of a native resident to changes in the institutional quality of the country of residence, $b_I^{ori}$ is the response of the trust level of an immigrant to changes in the institutional quality of the country of origin, and $b_I^{res}$ is the response of the trust level of an immigrant to changes in the institutional quality of the country of residence. The last column consists of estimates from equation (26), where $w = \frac{1}{1+\exp(-\gamma(E-c))}$ and $E$ is the household head’s years of education. Standard errors are in parentheses. ***, ** and * indicate significance at the 1%, 5% and 10% levels, respectively.

Table 3 Explaining stock market participation

The table reports the results for probit regressions of stock market participation on trust. In specification M1, the trust variable is the self-assessed level of trust extracted from the SHARE survey data. In specification M2, main explanatory variables of interest are the parts of trust that are explained and unexplained by institutional qualities, which are calculated according to equation (27), using the estimates of equation (26). M3 and M4 have the same main explanatory variables of interest, respectively, as M1 and M2, and include control variables. The controls are household income, wealth, years of education and birth year of household head, a dummy for being married (including co-habilitation), a male dummy, and level of risk aversion. The fifth column displays the average marginal effect of the variables across observations in M4. The last column of Panel B displays the average marginal effect of the explained part and the unexplained part of trust in M4 when these two variables are standardized. Standard errors are in parentheses. ***, ** and * indicate significance at the 1%, 5% and 10% levels, respectively.

Table 4 The marginal effects of institutional quality and education on participation, implied probability of participation, and actual participation rate

The first column shows the average marginal effects of institutional quality on stock market participation for native-borns and immigrants respectively. Here, $X^{res}$ is institutional quality in the country of residence, and $X^{ori}$ is institutional quality in the country of origin for immigrants. The last row shows the marginal effect of one extra year of education on the probability of stock market participation through the channel of trust for immigrants. Columns two and three report the average implied probability of participating in stock market and actual participation rate among all individuals, and then among natives, and among immigrants. The average implied probability is the average of individuals’ implied probabilities, which we calculate using equation (B2) (Appendix B).

Table 5 Controlling for other country specific characteristics

The table reports the results for our probit regressions of stock market participation on trust, where we control for gross national income (GNI) per capita and the ratio of stock market capitalization (MCAP) to gross domestic product (GDP). The trust variables are the part of trust explained by institutional quality and the part of trust unexplained by institutional quality, which are calculated according to equation (30), and based on estimates of equation (27). $D_N$ is a dummy variable for natives, and $D_I$ is a dummy variable for immigrants. $GNI^{res}$ and $GNI^{ori}$ are the GNI per capita of, respectively, the country of residence and the country of origin (for immigrants). $(MCAP/GDP)^{res}$ and $(MCAP/GDP)^{ori}$ are the ratio of MCAP to GDP of, respectively, the country of residence and the country of origin (for immigrants). Standard errors are in parentheses. ***, ** and * indicate significance at the 1%, 5% and 10% levels, respectively.

Figure 1 Institutional quality of the countries in the sample

The figure shows the institutional quality of the countries in the sample and for each country, it also shows the average institutional quality of its immigrants’ country of origin.
Figure 2 Average value of the trust variable

The figure shows the average values of the individual self-assessed level of trust for different countries. The trust variable ranges between zero and ten, where zero corresponds to the lowest level of trust. The averages are calculated separately for natives and immigrants in each country. The last two bars show the average values for all countries.
Figure 3 Actual rate of stock market participation in the sample

The figure shows the average rate of stock market participation across countries. The averages are calculated separately for natives and immigrants in each country. The last two bars show the average values over all the countries.
Figure 4 The relative importance of institutional quality of country of residence for immigrants’ level of trust

The figure shows the importance (weight) of institutional quality of country of residence for immigrants’ level of trust, relative to that of institutional quality of country of origin, at different levels of education and the sample means of the other explanatory variables. The relative importance (weight) of institutional quality of country of residence is calculated as a function of education in equation (26), for which estimated coefficients are reported in Table 2.
Figure 5 The average implied probabilities of participating in stock market among natives in 14 European countries.

This figure presents the average implied probability of participating in the stock market among natives in each country and its relation to institutional quality. We calculate implied probabilities, as described in equation (B1) in Appendix B, using the results from the estimation of the stock market participation equation (i.e., equation 28).
Figure 6 The implied probabilities of participating in stock market among actual immigrants

This figure presents the implied probability of participating in the stock market for each immigrant in the sample and its relation to the institutional quality in the country of residence and the institutional quality in the country of origin. We calculate implied probabilities, as described in equation (B1) in Appendix B, using the results from the estimation of the stock market participation equation (i.e., equation 28).
Figure 7 The predicted probability that an immigrant participates in the stock market

This figure shows the predicted probability that an immigrant participates in the stock market as a function of institutional quality in the country of origin and the country of residence. We calculate implied probabilities, as described in equation (B1) in Appendix B, using the results from the estimation of the stock market participation equation (i.e., equation 28).
Figure 8 Marginal effect of institutional qualities on immigrants’ stock market participation

The figure shows the marginal effects of institutional qualities in country of origin and country of residence on immigrants’ stock market participation for different levels of education. All variables are fixed at their sample means, except for the variable years of education, whose value we vary from 0 to 25.
Appendix A

A.1 Condition for myopic investors’ stock market participation

Here, we study the investment problem of a myopic investor and we show that the condition in (8) also applies to any myopic investor with strictly increasing, strictly concave and twice-continuously differentiable elementary utility function \( u \) satisfying \( \lim_{W \to 0} u'(W) = +\infty \).

Consider such an investor’s objective function at time \( t \) (where we have inserted the wealth constraints and use notation consistent with the one in the main text):

\[
\begin{align*}
g_t(\alpha_t) &\equiv \text{Prob}(\bar{R}_{t+1} = \varepsilon|D_t)u\left(W_t \left(R_f + \alpha_t(\varepsilon - R_f)\right)\right) \\
&+ \left(1 - \text{Prob}(\bar{R}_{t+1} = \varepsilon|D_t)\right) E_t \left[u\left(W_t \left(R_f + \alpha_t(\bar{R}^+_{t+1} - R_f)\right)\right]\right].
\end{align*}
\]

The investor also faces a no short-selling constraint, \( \alpha_t \geq 0 \).

The first- and second-order derivatives with respect to \( \alpha_t \) are given by

\[
\begin{align*}
g_t'(\alpha_t) &= \text{Prob}(\bar{R}_{t+1} = \varepsilon|D_t)u'\left(W_t \left(R_f + \alpha_t(\varepsilon - R_f)\right)\right) W_t(\varepsilon - R_f) \\
&+ \left(1 - \text{Prob}(\bar{R}_{t+1} = \varepsilon|D_t)\right) E_t \left[u'\left(W_t \left(R_f + \alpha_t(\bar{R}^+_{t+1} - R_f)\right)\right) W_t(\bar{R}^+_{t+1} - R_f)\right],
\end{align*}
\]

\[
\begin{align*}
g_t''(\alpha_t) &= \text{Prob}(\bar{R}_{t+1} = \varepsilon|D_t)u''\left(W_t \left(R_f + \alpha_t(\varepsilon - R_f)\right)\right) W_t^2(\varepsilon - R_f) \\
&+ \left(1 - \text{Prob}(\bar{R}_{t+1} = \varepsilon|D_t)\right) E_t \left[u''\left(W_t \left(R_f + \alpha_t(\bar{R}^+_{t+1} - R_f)\right)\right) W_t^2(\bar{R}^+_{t+1} - R_f)^2\right].
\end{align*}
\]

Since \( u \) is strictly concave, \( g_t''(\alpha_t) < 0 \) for all \( \alpha_t \), i.e., \( g_t \) is strictly concave in \( \alpha_t \). Therefore, the investor will participate in the stock market \( (\alpha_t > 0) \) if and only if \( g_t'(0) > 0 \), i.e., if and only if

\[
\text{Prob}(\bar{R}_{t+1} = \varepsilon|D_t)u'(W_tR_f)W_t(\varepsilon - R_f)
\]

\[
(A3)
\]
\[ + (1 - \text{Prob}(\tilde{R}_{t+1} = \epsilon|D_t)) u'(W_t R_f) W_t E_t[\tilde{R}_{t+1}^+ - R_f] > 0. \]

The above condition is equivalent to the one in (8).

A.2 Participation costs

In line with Guiso, Sapienza and Zingales (2008), we now introduce a fixed cost of participation in the stock market, \( f \). That is, wealth is decreased by \( f \) if the investor invests in the stock market. This induces wealth effects which interact with trust. Guiso, Sapienza and Zingales (2008) show that a small probability of fraud substantially increases the level of wealth required for stock market participation. Unless stated otherwise, we assume that

\[ \xi_t > \text{Prob}(\tilde{R}_{t+1} = \epsilon|D_t)/\left(1 - \text{Prob}(\tilde{R}_{t+1} = \epsilon|D_t)\right), \]

so that the investor would participate in the stock market in the absence of participation costs (see Equation 8 in Section 2 and also Appendix A.1). Defining the certainty equivalent stock return \( \tilde{R}_t \) implicitly through the relation

\[ \text{Prob}(\tilde{R}_{t+1} = \epsilon|D_t) u\left((W_t - f) \left(R_f + \alpha_t^*(\epsilon - R_f)\right)\right) \]

\[ + (1 - \text{Prob}(\tilde{R}_{t+1} = \epsilon|D_t)) E_t \left[u\left((W_t - f) \left(R_f + \alpha_t^*(\tilde{R}_{t+1} - R_f)\right)\right)\right] = \]

\[ u\left((W_t - f) \left(R_f + \alpha_t^*(\tilde{R}_t - R_f)\right)\right), \]

where \( \alpha_t^* \) is the optimal fraction of wealth allocated to the stock in the absence of participation costs if wealth is \((W_t - f)\), we can express the threshold level of wealth in terms of this quantity, as shown in the following proposition. Because of the assumption that \( \xi_t > \text{Prob}(\tilde{R}_{t+1} = \epsilon|D_t)/\left(1 - \text{Prob}(\tilde{R}_{t+1} = \epsilon|D_t)\right), \alpha_t^* \) is strictly positive.
Proposition 1: There exists a threshold level of wealth above which the investor will participate in the stock market. This threshold level of wealth is given by

\[ \tilde{W}_t = f \frac{R_f + \alpha_t^*(\tilde{R}_t - R_f)}{\alpha_t^*(\tilde{R}_t - R_f)}, \]  

where \( \tilde{R}_t \) is defined implicitly through equation (A4).

Proof: At the threshold value of wealth, we have that

\[
\text{Prob}(\tilde{R}_{t+1} = \epsilon | D_t) u \left( (\tilde{W}_t - f) \left( R_f + \alpha_t^*(\epsilon - R_f) \right) \right) + \left( 1 - \text{Prob}(\tilde{R}_{t+1} = \epsilon | D_t) \right) E_t \left[ u \left( (\tilde{W}_t - f) \left( R_f + \alpha_t^*(\tilde{R}_{t+1} - R_f) \right) \right) \right] = u(\tilde{W}_t R_f),
\]

and thus,

\[
u \left( (\tilde{W}_t - f) \left( R_f + \alpha_t^*(\tilde{R}_t - R_f) \right) \right) = u(\tilde{W}_t R_f).
\]

The result then follows from the strict monotonicity of \( u \).

The above proposition shows that participation costs induce wealth effects and we determine the threshold level of wealth required for stock market participation. More interestingly, as we show in the following proposition, the learning mechanism interacts with the participation costs in such a way that having a nonzero prior probability of fraud increases the threshold value of wealth required for stock market participation.

Proposition 2: The higher the prior probability of fraud, the higher the threshold value of wealth required for stock market participation.

Proof: Suppose that \( \tilde{\theta}_0 > \bar{\theta}_0 \) and suppose also that \( \tilde{W}_t \) is the threshold value of wealth corresponding to the lower prior (\( \bar{\theta}_0 \)), meaning that
\[ Prob(\bar{R}_{t+1} = \varepsilon | D_t; \bar{\theta}_0) u \left( (\bar{W}_t - f) \left( R_f + \alpha^*_t (\varepsilon - R_f) \right) \right) \] (A8)

\[ + \left( 1 - Prob(\bar{R}_{t+1} = \varepsilon | D_t; \bar{\theta}_0) \right) E_t \left[ u \left( (\bar{W}_t - f) \left( R_f + \alpha^*_t (\bar{R}_{t+1}^+ - R_f) \right) \right) \right] = u(\bar{W}_t R_f). \]

With a higher prior probability of fraud, the expected utility that can, ceteris paribus, be achieved in the absence of participation costs when wealth is \((W_t - f)\) must be lower:

\[ Prob(\bar{R}_{t+1} = \varepsilon | D_t; \bar{\theta}_0) u \left( (\bar{W}_t - f) \left( R_f + \alpha^*_t (\varepsilon - R_f) \right) \right) \] (A9)

\[ + \left( 1 - Prob(\bar{R}_{t+1} = \varepsilon | D_t; \bar{\theta}_0) \right) E_t \left[ u \left( (\bar{W}_t - f) \left( R_f + \alpha^*_t (\bar{R}_{t+1}^+ - R_f) \right) \right) \right] < \]

\[ Prob(\bar{R}_{t+1} = \varepsilon | D_t; \bar{\theta}_0) u \left( (\bar{W}_t - f) \left( R_f + \alpha^*_t (\varepsilon - R_f) \right) \right) \]

\[ + \left( 1 - Prob(\bar{R}_{t+1} = \varepsilon | D_t; \bar{\theta}_0) \right) E_t \left[ u \left( (\bar{W}_t - f) \left( R_f + \alpha^*_t (\bar{R}_{t+1}^+ - R_f) \right) \right) \right] = u(\bar{W}_t R_f). \]

Therefore, by Proposition 1, the threshold value of wealth corresponding to the prior \(\bar{\theta}_0\) must be higher than \(\bar{W}_t\). That is, \(\bar{W}_t > W_t\).

Conversely, adding participation costs to our learning model lowers the value of the prior that triggers nonparticipation, as shown in the proposition below.

**Proposition 3:** Adding a participation cost lowers the threshold value of the prior probability of fraud that triggers nonparticipation.

**Proof:** Suppose that \(\hat{\theta}_0\) triggers participation in the absence of participation costs. That is,

\[ Prob(\bar{R}_{t+1} = \varepsilon | D_t; \hat{\theta}_0) u \left( W_t \left( R_f + \alpha^*_t (\varepsilon - R_f) \right) \right) \] (A10)

\[ + \left( 1 - Prob(\bar{R}_{t+1} = \varepsilon | D_t; \hat{\theta}_0) \right) E_t \left[ u \left( W_t \left( R_f + \alpha^*_t (\bar{R}_{t+1}^+ - R_f) \right) \right) \right] = u(W_t R_f). \]
With the same prior $\hat{\theta}_0$, the expected utility achieved in the absence of participation costs when wealth is $(W_t - f)$ must be lower:

$$Prob(\bar{R}_{t+1} = \varepsilon|D_t; \hat{\theta}_0)u\left((W_t - f)\left(R_f + \alpha_{t}^{**}(\varepsilon - R_f)\right)\right)$$

$$+ \left(1 - Prob(\bar{R}_{t+1} = \varepsilon|D_t; \hat{\theta}_0)\right)E_t\left[u\left((W_t - f)\left(R_f + \alpha_{t}^{**}(\bar{R}_{t+1} - R_f)\right)\right]\right] <$$

$$Prob(\bar{R}_{t+1} = \varepsilon|D_t; \hat{\theta}_0)u\left(W_t\left(R_f + \alpha_{t}^{*}(\varepsilon - R_f)\right)\right)$$

$$+ \left(1 - Prob(\bar{R}_{t+1} = \varepsilon|D_t; \hat{\theta}_0)\right)E_t\left[u\left(W_t\left(R_f + \alpha_{t}^{*}(\bar{R}_{t+1} - R_f)\right)\right]\right] = u(W_tR_f).$$

Now, the expected utility that can be achieved is decreasing in the posterior probability of fraud, $Prob(\bar{R}_{t+1} = \varepsilon|D_t; \hat{\theta}_0)$, and the posterior probability of fraud is, in turn, increasing in the prior probability of fraud, $\theta_0$, meaning that, in the case when there are participation costs, the prior probability that triggers participation must be lower than $\hat{\theta}_0$. 
Appendix B: Implied probabilities and the derivation of marginal effects

We use an ordered probit model to estimate (25) and (26) by assuming the following censoring mechanism:

\[ T_i = j \text{ if } \mu_{j-1} < T_i^* \leq \mu_j, \]

where \( j = 0, 1, 2 \ldots 10 \), since in SHARE, the variable trust \( T \) is an ordinal variable that goes from zero (low trust) to ten (high level of trust). The implied probabilities of different levels of trust are obtained as

\[
Prob[T_i = j|X_i^T] = Prob[\varepsilon_i \leq \mu_j - \text{func}(X_i^T)] - Prob[\varepsilon_i \leq \mu_{j-1} - \text{func}(X_i^T)] \tag{B1}
\]

\[ = F(\mu_j - \text{func}(X_i^T)) - F(\mu_{j-1} - \text{func}(X_i^T)), \text{ for } j = 1, 2, \ldots 10, \]

where \( \mu_{-1} = -\infty, \mu_{10} = +\infty \), \( X_i^T \) is the vector of all the explanatory variables for individual \( i \) in equation (26) and \( \text{func}(\cdot) \) is the function from institutional quality to trust specified in equation (26).

The implied probability that individual \( i \) participates in the stock market is obtained from the probit model in equation (28):

\[
Prob[y_i = 1|X_i^p] = 1 - F(-\alpha'X_i^p), \tag{B2}
\]

where \( X_i^p \) is the vector of all the explanatory variables (including one) for individual \( i \) in equation (28) and \( \alpha \) is the corresponding vector of parameters.

We compute the following marginal effects for the variables of the model in equation (26).

a) Marginal effect of a change in institutional quality of the country of residence for natives \((D_{N,i} = 1)\) on stock market participation:

\[
\frac{\partial Prob[y_i = 1|X_i^p]}{\partial X_i^{res}} = \frac{\partial Prob[y_i = 1|X_i^p]}{\partial T_i^{expl}} \cdot \frac{\partial T_i^{expl}}{\partial X_i^{res}}. \tag{B3}
\]

The first term on the right hand side is given by
\[
\frac{\partial \text{Prob}[y_i = 1|X_i^p]}{\partial T_i^{\text{expl}}} = a_1 f(\alpha'X_i^p),
\]  
(B4)

and, according to the definition of \( T_i^{\text{expl}} \) in equation (27), the second term is given by

\[
\frac{\partial T_i^{\text{expl}}}{\partial X_i^{\text{res}}} = \frac{\partial \sum_{j=1}^{J} \text{Prob}[T_i = j|X_i^T].j}{\partial X_i^{\text{res}}} = \sum_{j=1}^{J} \left( \frac{\partial F(\mu_j - \text{func}(X_i^T))}{\partial X_i^{\text{res}}} - \frac{\partial F(\mu_{j-1} - \text{func}(X_i^T))}{\partial X_i^{\text{res}}} \right) j.
\]  
(B5)

For natives, the above expression is equal to

\[
\frac{\partial T_i^{\text{expl}}}{\partial X_i^{\text{res}}} = -b_N \sum_{j=1}^{J} \left( f(\mu_j - \text{func}(X_i^T)) - f(\mu_{j-1} - \text{func}(X_i^T)) \right) j.
\]  
(B6)

Thus, we have that

\[
\frac{\partial \text{Prob}[y_i = 1|X_i^p]}{\partial X_i^{\text{res}}} = -b_N a_1 f(\alpha'X_i^p),
\]  
(B7)

where

\[
H_i = \sum_{j=1}^{J} \left( f(\mu_j - \text{func}(X_i^T)) - f(\mu_{j-1} - \text{func}(X_i^T)) \right) j.
\]

b) Marginal effect of a change in institutional quality of the country of residence for immigrants (\( D_{i,i} = 1 \)):

\[
\frac{\partial \text{Prob}[y_i = 1|X_i^p]}{\partial X_i^{\text{res}}} = \frac{\partial \text{Prob}[y_i = 1|X_i^p]}{\partial T_i^{\text{expl}}} \cdot \frac{\partial T_i^{\text{expl}}}{\partial X_i^{\text{res}}}.
\]  
(B8)

The first term is given by equation (B4) and the second term can be obtained from equation (B5) for immigrants as
\[ \frac{\partial T_i^{\text{expl}}}{\partial X_i^{\text{res}}} = -b_i \omega \sum_{j=1}^{J} \left( f(\mu_j - \text{func}(X_i^j)) - f(\mu_{j-1} - \text{func}(X_i^j)) \right). j \]  

(B9)

Thus, we have that

\[ \frac{\partial \text{Prob}[y_i = 1|X_i^p]}{\partial X_i^{\text{res}}} = -b_i w_i H_i a_i f(\alpha' X_i^p). \]  

(B10)

c) Marginal effect of a change in institutional quality of the country of origin for immigrants 

\((D_{i,l} = 1)\):

\[ \frac{\partial \text{Prob}[y_i = 1|X_i^p]}{\partial X_i^{\text{org}}} = \frac{\partial \text{Prob}[y_i = 1|X_i^p]}{\partial T_i^{\text{expl}}} \cdot \frac{\partial T_i^{\text{expl}}}{\partial X_i^{\text{org}}}. \]  

(B11)

The first term is given by equation (B4) and the second term can be written as

\[ \frac{\partial T_i^{\text{expl}}}{\partial X_i^{\text{org}}} = -b_i (1 - \omega) \sum_{j=1}^{J} \left( f(\mu_j - \text{func}(X_i^j)) - f(\mu_{j-1} - \text{func}(X_i^j)) \right). j. \]  

(B12)

Thus, we have that

\[ \frac{\partial \text{Prob}[y_i = 1|X_i^p]}{\partial X_i^{\text{org}}} = -b_i (1 - w_i) H_i a_i f(\alpha' X_i^p). \]

d) Marginal effect of a change in education for immigrants \((D_{i,l} = 1)\) through its effect on the explained part of trust:

\[ \frac{\partial \text{Prob}[y_i = 1|X_i^p]}{\partial E_i} = \frac{\partial \text{Prob}[y_i = 1|X_i^p]}{\partial T_i^{\text{expl}}} \cdot \frac{\partial T_i^{\text{expl}}}{\partial w_i} \cdot \frac{\partial w_i}{\partial E_i}. \]  

(B13)

The first term is again given by equation (B4), whereas the second term is given by

\[ \frac{\partial T_i^{\text{expl}}}{\partial w_i} = -b_i (X_i^{\text{res}} - X_i^{\text{org}}) \sum_{j=1}^{J} \left( f(\mu_j - \text{func}(X_i^j)) - f(\mu_{j-1} - \text{func}(X_i^j)) \right). j \]  

(B14)
\[ = -b_i (X_i^{res} - X_i^{org}) H_i, \]

and the third term is given by

\[
\frac{\partial w_i}{\partial E_i} = \frac{\gamma \exp(-\gamma(E_i - c))}{\left(1 + \exp(-\gamma(E_i - c))\right)^2}.
\]  

(B15)

Thus, we get that

\[
\frac{\partial \text{Prob}[y_i = 1|X_i^p]}{\partial E_i} = -b_i (X_i^{res} - X_i^{org}) H_i \delta_i a_1 f(\alpha X_i^p),
\]  

(B16)

where

\[
\delta_i = \frac{\gamma \exp(-\gamma(E_i - c))}{\left(1 + \exp(-\gamma(E_i - c))\right)^2}
\]
Institutional Quality, Trust and Stock Market Participation: Learning to Forget

HOSSEIN ASGHARIAN | LU LIU AND FREDERIK LUNDTOFTE

This paper explores the relation between institutional quality, trust and stock market participation. In our theoretical motivation, agents update their beliefs in a Bayesian manner based on their historical observations on frauds and they choose to invest in the stock market if their subjective probability of fraud is sufficiently low. In accordance with this theoretical motivation, we develop an empirical model, which tests the hypothesis that higher institutional quality is likely to lead to a higher level of trust, together with the hypothesis that when the level of trust is sufficiently high, agents choose to invest in the stock market. We use a large sample of European (SHARE survey) data on households residing in fourteen European countries that have a large variation in institutional quality. We find that institutional quality has a significant effect on trust and that trust (particularly the part that is explained by institutional quality) in turn significantly affects stock market participation. Moreover, our model takes into account the learning process of immigrants, who experience a dramatic change in institutional quality. We find that the probability that an immigrant participates in the stock market increases both with the institutional quality of the country of residence and that of the country of origin. However, on average, the former is more influential than the latter. We also find that immigrants with a higher level of education adapt their level of trust faster to the institutional environment of the country of residence than those with a lower level of education. The impact of the institutional quality of the immigrants’ country of residence on stock market participation, relative to that of their country of origin, tends to increase with education.

**Key words:** institutional quality, learning, trust, limited participation puzzle

THE KNUT WICKSELL CENTRE FOR FINANCIAL STUDIES

The Knut Wicksell Centre for Financial Studies conducts cutting-edge research in financial economics and related academic disciplines. Established in 2011, the Centre is a collaboration between Lund University School of Economics and Management and the Research Institute of Industrial Economics (IFN) in Stockholm. The Centre supports research projects, arranges seminars, and organizes conferences. A key goal of the Centre is to foster interaction between academics, practitioners and students to better understand current topics related to financial markets.
